Fifteen-minute consultation: when is a seizure not a seizure? Part 2, the older child

Mohamed OE Babiker,1 Manish Prasad2

ABSTRACT
Paroxysmal non-epileptic events (PNEs) refer to episodic changes in behaviour, sensation or consciousness that lead to unusual movements, which may resemble epileptic seizures, but are not, due to excessive neuronal firing in the cerebral cortex. A significant proportion of patients seen in epilepsy clinics do not actually have epilepsy. Therefore, it is paramount for clinicians to be able to recognise these transient non-epileptic events in order to avoid unnecessary antiepileptic treatments and to provide appropriate management as required. These PNEs can be observed within the context of a neurological disorder such as migraine or with no direct neurological basis such as simple tics. In this review, we have described common PNEs presenting in school-age children and adolescents alongside the clinical approach to differentiate them from epileptic seizures. PNEs occurring in infancy and younger children have been covered in our first review of this series.

INTRODUCTION
Paroxysmal neurological or non-neurological events in children and adolescents that mimic epileptic seizures (ES) are common. These range from migraine to simple tics. Epilepsy, by virtue of its episodic nature, is by far the most important consideration in the diagnostic paradigm.

One of the reasons why epilepsy misdiagnosis is common is the potential difficulty in recognising these non-epileptic events. Over reliance on investigations such as the standard electroencephalogram (EEG) is also contributory. Non-specific EEG abnormalities can be seen in normal children, and a normal interictal EEG does not exclude epilepsy on the other hand.1 In fact, the commonly asked question ‘is it epilepsy?’ can rarely be answered by a 20 min EEG recording, making this an inappropriate request on most occasions.2 Thus, the most helpful approach is of an informative history from an eyewitness combined with a video account when possible with the occasional use of a prolonged EEG video telemetry in difficult cases.

In the first instance, health professionals should have a working knowledge of the semiological features of ES to confidently diagnose paroxysmal non-epileptic events (PNEs). Along with clinical experience, accesses to educational websites that contain teaching videos serve such a purpose. An example is the International League Against Epilepsy sponsored free website (https://www.epilepsydiagnosis.org). It is not uncommon these days for parents to ‘Google’ and look up online videos (eg, on YouTube) that might (or might not) be relevant to their child’s episodes even before coming to the clinic appointment, and clinicians should be mindful of this.

In this article, we present the commonly referred PNEs that may imitate ES in school-age children and adolescents. A diagnostic approach is also discussed, focusing on how these conditions are identified. Detailed pathophysiology and management are beyond the scope of this paper.

SYNCOPE
Syncope can be defined as a transient loss of consciousness due to a ‘sudden decrease in cerebral perfusion with oxygenated blood, either from a reduction in cerebral blood flow itself or from a drop in its oxygen content, or a combination of these’.3 This is more common in adolescents than any other age group, and up to 15% of children will experience at least one episode before 18 years of age.4
Precipitants may include sudden change in posture, acute emotional upset, hair grooming and micturition. Presyncopal symptoms include dizziness, nausea, feeling hot, sudden ‘grey ing out’, a rushing noise in the ears and vague abdominal discomfort. These symptoms are followed by a sensation of confusion and loss of consciousness. Up-rolling of the eyes, urinary incontinence and shaking of limbs can all occur during syncope, potentially causing diagnostic confusion with ES. Syncopal attacks associated with tonic, clonic, tonic-clonic and hypermotor movements are called convulsive syncope. Recovery may be quick, within seconds in ‘mild’ syncope, or there may be prolonged postictal confusion or sleeping ‘severe’ syncope.

There is no one single clinical feature that reliably differentiates between a convulsive syncope attack and an ES. Tongue biting was found to have a specificity of 96% and a sensitivity of 33% for ES in one systemic review. Biting at the tip of the tongue was more indicative of convulsive syncope, whereas biting at the tongue sides was seen in ES as demonstrated in one paediatric study. Urinary incontinence has no value in differentiating ES from other paroxysmal events, including syncope.

Blood pressure should always be recorded in addition to a 12-lead ECG. A cardiac cause is suspected if syncope is exercise related or sleep related, or if there is a family history of sudden death, abnormal cardiovascular examination or abnormal ECG. In these cases, referral to cardiology is recommended. Other investigations, including head-up tilt test, are occasionally required if doubt about diagnosis persists, or if the attacks are very severe or frequent.

TICS

Tics are the most common involuntary paroxysmal movements observed in children with a nearly 20% prevalence among school-age children, according to one survey. Typical age of onset is between 4 and 8 years. Tics can be motor or vocal. Common motor tics include eye blinking, head and neck craning, facial grimace, arm twitching and shoulder shrugging. Common vocal tics include throat clearing, squeaking noises, sniffing and coughing. Characteristically, tics are preceded by a premonitory urge, sometimes called a ‘tic alert’, with a relative sense of relief following the tic. Tics tend to disappear during sleep, are exaggerated by anxiety or stress. Their severity and frequency follow a waxing and waning course, with most children eventually growing out of their tics. It is not uncommon for children to present with an explosive onset of tics, which can, understandably, be a source of anxiety for parents and clinicians alike.

Comorbid conditions may include attention deficit hyperactivity disorder, obsessive-compulsive behaviours and learning disability. Differentiation from ES is by obtaining a history of the ‘tic alert’, and the partial ability to suppress the tic in addition to the stereotyped behaviours explained above.

NON-EPILEPTIC ATTACKS

Non-epileptic attacks (NEAs) are episodes of variable motor, sensory and cognitive symptoms secondary to impairment of self-control, and not caused by abnormal cortical neuronal discharges. There is no universal agreement on the best terminology, and many have been used such as non-ES, pseudo seizures, psychogenic non-ES, functional/hysterical seizures, dissociative seizures and conversion seizures. However, care must be exercised as some of these terms are confusing and even pejorative.

In a recent British Paediatric Surveillance Unit study that looked at the incidence of non-transient conversion disorders in children aged 7–15 years in the UK and Ireland, ‘non-ES’ were diagnosed in 40% of those diagnosed. A prospective study found that 13% of the children with PNEs referred to a secondary care clinic had ‘psychogenic seizures’ with a median age of 12 years. NEAs are common in children and young people with epilepsy, which can cause a diagnostic dilemma in some cases.

A diagnosis of NEAs is serious. Several studies have shown that quality of life is significantly lower in
patients with NEAs in comparison with those with epilepsy. Anxiety, mood disorders, emotional problems and depression are over-represented in this group of children. More alarmingly, an adult study showed that 27% of patients with ‘psychogenic non-ES’ had episodes that mimicked status epilepticus, and were admitted to an intensive care unit.

There is no single clinical feature that differentiates between NEAs and ES. Broadly speaking, ES are usually unprovoked, have an abrupt onset, brief and highly stereotyped. Boxes 1 and 2 outline some of the features that, collectively, have a higher sensitivity for NEAs, as well as the features that are not helpful in differentiating between both entities.

A few studies have demonstrated that apparent lack of responsiveness with subtle motor phenomena is more common in younger patients, whereas convulsive movements are seen in older children.

The following are practical points to consider:

▸ A request can be made in the appointment letter asking the parents to bring video footage of the events in question.

▸ Allow time to see the child/young person separately.

▸ Are there any triggers or contexts in which the events are likely to happen within (ie, stressful situations)?

▸ A detailed description of the attacks. Patients commonly do not give detailed description of the attack itself and instead focus on the details surrounding it.

▸ Explore what the patient/parents think is wrong with them.

### Box 2 Unhelpful features in differentiating non-epileptic attacks from epileptic seizures (ES)

- Reported aura
- Stereotyped (or non-stereotyped) movements
- Urine (or faecal) incontinence
- Report of tongue biting (except for marks of biting on the side of the tongue in ES)
- Pelvic thrusting
- Self-injury
- Postictal confusion
- Autonomic dysfunction such as tachycardia and pupil dilatation
- Male gender or younger age
- A normal standard electroencephalogram
- Postictal serum prolactin or plasma creatine kinase levels
- A prior diagnosis of epilepsy
- Response to antiepileptic drugs (possibility of a placebo effect)

### Table 1 Migraine variants that can potentially be misdiagnosed as epilepsy (diagnostic criteria for each condition are described in the International Headache Society Classification (ICHD-II) website: http://ihs-classification.org/en/)

</tbody>
</table>
A history of previous functional symptoms might support the diagnosis. However, be sensitive to previous ‘negative’ experiences from encounters with other health professionals who might have implied to them that ‘it’s all in their head!’

A prior diagnosis of ‘epilepsy’ does not mean that the events in question are necessarily ‘epileptic’. Between 10% and 30% of adults with epilepsy have associated NEAs.18

Questions about potential adverse social circumstances (such as bullying and maltreatment), stress and anxiety

### Table 2 Examples of non-epileptic events encountered in children with neurodisability

<table>
<thead>
<tr>
<th>Condition</th>
<th>Examples of associated paroxysmal non-epileptic events</th>
</tr>
</thead>
</table>
| Autistic spectrum disorder | ► Motor stereotypes  
► Self-stimulatory behaviours (eg, compulsive Valsalva manoeuvre leading to reflex anoxic seizures)  
► Sensory processing issues (eg, unusual visual experiences)                                                                 |
| Cerebral palsy (all types) | ► Associated dystonia (repetitive twisting movements)  
► Status dystonicus  
► Dykinetic movement disorders (eg, choreoathetoid movements)  
► Agitation episodes manifested by hypermotor or tonic spasm features (with or without autonomic accompaniments) due to undiagnosed or undertreated comorbidities that can cause pain such as gastro-oesophageal reflux, constipation, orthopaedic problems, dental pain … etc. Every effort should be made to assess for pain and to rule these causes out |
| Post brain injury          | ► Subcortical myoclonus  
► Tonic spasms  
► Paroxysmal autonomic instability with dystonia: tachycardia, hyperthermia, hypertension, agitation and extensor posturing |
| Intellectual disability    | ► Timeout phenomenon, in which, the child would appear to be staring blankly and become motionless. This is usually situational. It may be mistaken for absence seizures  
► Self-stimulatory behaviours (eg, rocking, spinning … etc)                                                                 |
| Rett syndrome              | ► Hand stereotypes  
► Syncopal attacks secondary to hyperventilation, breath holding and prolonged QT interval  
► Abnormal behaviours (eg, ‘screaming fits’)                                                                                                                                   |
| Neiman–Pick type C         | ► Drop attacks secondary to cataplexy (sudden loss of muscle tone in response to intense emotions like laughter)                                                                |
| Drug-related movement disorders | ► Tics and motor stereotypes: can complicate the treatment course with methylphenidate  
► Oculogyric crisis: presents with dystonic ocular movements such as upward deviation of the eyes, periorbital twitching and prolonged staring. Agents may include domperidone, metoclopramide and carbamazepine  
► Tardive dyskinesia: characterised by rhythmic movements of the tongue, face, trunk and extremities. Can complicate prolonged treatment (>3 months) with a dopamine antagonist such as risperidone  
► Status dystonicus secondary to sudden withdrawal of baclofen or benzodiazepines                                                                                           |
are better left to the end after a good rapport has been built with the patient and parents.

> Seek information widely from school and other professionals involved.

The history alone or in combination with a video recording is usually sufficient to secure the diagnosis. A standard interictal EEG is not helpful, and should not be requested as it has the potential to contribute to diagnostic errors. Where uncertainty remains, video telemetry monitoring in a specialist centre is considered the ‘gold standard’.

**MIGRAINE**

Individually, migraine and epilepsy are the most common paediatric neurological disorders seen in practice. Some migraine variants can present with episodic neurological symptoms such as disturbance of consciousness that can be confused with seizures. There is an increased frequency of migraine in children, with certain epilepsy syndromes such as benign rolandic epilepsy and Panayiotopoulos syndrome. Headache, which is usually the predominant symptom in migraine, is also frequently experienced in association with seizures. In a recent prospective paediatric study, both preictal and postictal headaches were reported in one-third of patients with epilepsy, more commonly reported in association with focal seizures.

Migraine was prevalent in one-fifth of the patients in that study. Some of the migraine variants in children, which can cause diagnostic confusion, are presented in table 1.

Despite their similarities, migraine and epilepsy are distinct disorders with important differences. A thorough careful history is paramount. Box 3 highlights important points, which can be helpful.

### SEIZURE MIMICS IN CHILDREN WITH NEURODISABILITY AND PSYCHOLOGICAL DISORDERS

Although epilepsy is common in this heterogeneous group of children with neurodevelopmental disorders, seizure mimics are also common, and can be a source of diagnostic confusion. Table 2 provides examples of non-epileptic episodes associated with neurodisability. Equally, children with psychological disorders may present with episodic features that mimic seizures. These are described in table 3.

### CONCLUSION

PNEs are a common source of misdiagnosis of epilepsy in older children and adolescents. A thorough knowledge of the various seizure mimics at all age groups is vital in avoiding the wrong diagnosis, inappropriate investigations and management.
