EVIDENCE BASED UPDATE ON THE MANAGEMENT OF ACNE

Jane Ravenscroft

Arch Dis Child Educ Pract Ed 2005;90:ep98–ep101. doi: 10.1136/adc.2004.071183

Acne is an extremely common condition, affecting up to 80% of adolescents. Many cases are mild and may be considered “physiological”, but others can be very severe and lead to permanent scarring. Paediatricians will frequently encounter acne in their practice, and have an important role in identifying and advising patients who require treatment.

This review focuses on the practical management of acne from a paediatric perspective, with an emphasis on relating treatment decisions to currently available evidence. Many clinical trials of acne treatment have been carried out in the last 25 years, but they are of variable quality. Hence, there are grey areas, where treatment has to be guided by consensus opinion or clinical experience until better evidence is available.

CLINICAL FEATURES AND AETIOLOGY

Acne is a disease of pilosebaceous follicles. Under the influence of androgens, usually around puberty, the sebaceous glands enlarge and produce excess sebum. At the same time, keratinocytes in the sebaceous duct proliferate and cause blockage. These events lead to comedone formation. As a secondary event, *Propionibacterium acnes* (*P acnes*) colonise the comedones causing inflammation, which leads to papules and pustules.

Clinically, acne usually affects the face first, with the back and chest affected in more severe cases. The lesions seen are blackheads (open comedones), whiteheads (closed comedones), papules, pustules and sometimes nodules, cysts, and scars.

TREATMENT

Treatment is influenced by the type of lesions, severity, sex and age of patient, psychological impact of the disease, and presence of scarring.

In exceptional circumstances where there is abnormal androgen production, or an external cause, treatment is directed to the underlying cause.

All acne treatments take up to 12 weeks to reach maximum benefit, and should usually be continued for several months. Education regarding the natural history of acne and expectations of treatment will improve compliance.

TREATMENT OF MILD ACNE

Case history A

Michael, who is 13, has been attending your clinic with an unrelated problem. He is on no medication. Mum mentions that he is getting a few teenage spots on his forehead and nose, and wants to know whether cutting out chocolate and washing more frequently would help. Also, is it worth buying acne preparations from the chemist for Michael to use?

Diet

Although it is widely believed that foods such as chocolate and sweets aggravate acne, there is no evidence to support this. In a study of chocolate ingestion among acne sufferers, acne was unaffected in the majority, improved in a few, and worsened in a few.¹ Acne sufferers should be reassured that a normal healthy diet is best.

Skin care

There is no evidence that lack of washing is associated with acne, or that frequent washing improves it. Acne patients should wash their skin daily using warm water ± ordinary soap. Antibacterial soaps, which contain agents such as chlorhexidine and triclosan, do not affect *P acnes*. Abrasives should be avoided as they can aggravate inflammation. Make up and moisturisers, if needed, should be oil-free and non-comedogenic.²

Topical salicylic acid

Many acne washes and topical preparations on sale to the public contain salicylic acid as the active ingredient. This is an anti-keratolytic with some anti-comedone effects, which is widely considered to be of some effect in mild acne, but there is a lack of evidence of efficacy from randomised controlled trials.

Topical benzoyl peroxide

Benzoyl peroxide is a cheap, safe, and effective treatment for acne, which can be bought “over the counter” in the UK. It is a powerful antimicrobial agent that rapidly destroys *P. acnes*. This has a secondary effect of reducing comedones. It has been shown to be more effective than topical antibiotics in several studies,³ and is not affected by bacterial resistance. A recent randomised controlled trial of five antimicrobial regimens for treatment of mild to moderate inflammatory facial acne in the community showed moderate or greater improvement at 18 weeks in 60% of patients on benzoyl peroxide alone, and concluded it was the most cost effective treatment.⁴

Benzoyl peroxide is available in a variety of formulations and concentrations ranging from 1–10%. Treatment should be applied once or twice daily to the entire area affected by acne. The main side effect of benzoyl peroxide is skin irritation and dryness, which can be severe enough to preclude use. Patients also need to be warned about bleaching of clothes.

Benzoyl peroxide washes can be effective if large areas of coverage are needed, and are less irritant than “leave on” preparations.

TREATMENT OF MODERATE ACNE

Case A (continued)

At annual review one year later, aged 14, Michael’s acne is much worse. He has a lot of blackheads and whiteheads on his face, and many inflamed lesions on his back and chest. He has been using benzoyl peroxide 5% gel on his face on most days but this is not really helping. What would you do next?

A more detailed history should be taken. Some drugs have been associated with exacerbation of acne (table 1). A strong family history of acne is a predictor of more severe disease.

If no exacerbating factors are identified, there is a choice of treatments that can be used. All of these are best used in combination with benzoyl peroxide, if tolerated.

Table 1 Drug and external factors reported to cause acne/acneiform eruptions

Hormones and steroids	External factors
Androgens	Cosmetics
Anabolic steroids	Pomades
Oral and topical steroids	Machine oils and tars
Gonadotropins	Mechanical trauma, e.g. head bands
Epileptic drugs	
Phenobarbital	
Phenytoin	
Antituberculous drugs	
Isoniazid	
Rifampicin	

Topical retinoids

Randomised controlled studies have shown that retinoids reduce comedones and inflammatory lesions by 40–80%.² Many formulations and strengths of retinoids are available on prescription. The most widely used is tretinoin, which is available in strengths of 0.01% and 0.025%.

All retinoids cause skin irritation, which may preclude use in some patients. This is less pronounced with second generation retinoids—for example, adapalene—and can be reduced by techniques such as alternate day application or short contact use—that is, washed off after one hour.

Topical retinoids may be used alone, but are more effective when combined with a topical antibacterial, either benzoyl peroxide or an antibiotic.^{2–5}

Topical antibiotics

Clindamycin and erythromycin are available in topical formulations and are effective against inflammatory acne.⁶ They are not generally recommended as monotherapy because of (a) slow onset of action, (b) limited efficacy against non-inflammatory lesions, and (c) potential for emergence of resistant *P. acnes* and *Staphylococcus aureus*. Emergence of resistance is reduced by limiting treatment to eight weeks at a time, and combining with benzoyl peroxide.²

Topical azelaic acid

Azelaic acid cream 20% is a naturally occurring dicarboxylic acid with antibacterial and anti-keratinising effects. It has been reported to have similar efficacy to benzoyl peroxide and retinoids in reducing inflammatory lesions and comedones,⁷ but is less widely used. It causes little skin irritancy, and is therefore particularly useful for patients who cannot tolerate benzoyl peroxide or retinoids.

Oral antibiotics

Oral antibiotics were the mainstay of acne treatment for many years.

They are particularly useful when large areas of the body are involved with acne, or when patients cannot tolerate or dislike topical therapy.⁸

Tetracyclines (tetracycline, oxytetracycline, minocycline, lymecycline, and doxycycline), macrolides, trimethoprim, clindamycin, and quinolones are all effective at eliminating *P. acnes*, and reducing inflammatory lesions in acne. Oxytetracycline should generally be the first choice of oral antibiotic in a dose of 1 g per day. A Cochrane systematic review⁹ has concluded that there is no justification for using minocycline first line because of lack of evidence for greater efficacy, concerns about safety, and higher cost. There may be some justification for using other second generation tetracyclines—for example, lymecycline—because it is taken once daily, and absorption is unaffected by food.

Tetracyclines are contraindicated in children under 12 years because they cause staining of developing teeth.

Antibiotic resistance of *P. acnes* is an increasing problem. Up to 50% of patients carry *P. acnes* resistant to erythromycin, and up to 20% resistant to tetracycline. This can be associated with therapeutic failure.

In an attempt to reduce resistance, it is recommended that antibiotics should be used for no more than six months at a time, and that benzoyl peroxide is used concurrently where possible. The addition of a retinoid may be beneficial to reduce non-inflamed lesions.⁹

Table 2 Hormonal investigations for acne

Investigation	Possible cause of elevation
Total and free testosterone	Polycystic ovarian syndrome Rarely, ovarian tumours
Serum dehydroepiandrosterone (DHEAS)	Adrenal tumour or congenital adrenal hyperplasia
Luteinising hormone/follicular stimulating hormone (LH/FSH) ratio	Polycystic ovarian syndrome
17-hydroxyprogesterone	Congenital adrenal hyperplasia
Prolactin	Hyperprolactinaemia
24 hour urinary free cortisol	Cushing's disease or syndrome

Indicated in females with signs of hyperandrogenism (hirsutism, irregular menses, androgenetic alopecia), or in patients with poor response to treatment.

A recent randomised controlled trial has shown that topical benzoyl peroxide and topical benzoyl peroxide/erythromycin combinations are similar in efficacy to oral oxytetracycline and minocycline.⁴ This, and increasing concerns about bacterial resistance, put into question the widespread use of oral antibiotics for acne.

TREATMENT OF SEVERE ACNE

Case B

Mandy, who is 15 years old, has been under your care with asthma for several years. She attends with her mother who is very concerned because Mandy has stopped going out because she is self conscious about her spots. Examination of Mandy's skin reveals multiple pustules and comedones on the face, back, and chest. There are also some nodules and cysts on her cheeks. What advice would you give?

A more detailed history is needed. Mandy's activities are being affected by her acne. Has she any other features of depression? Is there any evidence of scarring? Are there any features of androgen excess? Are corticosteroid drugs exacerbating her acne? Is Mandy sexually active?

Menstrual irregularities, hirsutism, or signs of hyperandrogenism should prompt hormonal investigation (table 2). Effort should be made to reduce oral steroids if possible. Technique of inhaled steroid should be checked as poor technique can lead to perioral acne.

Treatment needs to be aggressive in this situation, to restore self confidence and prevent scarring.

Initially, topical treatment $\pm$ oral antibiotic should be started as for moderate acne. Hormonal treatment should be discussed. In the presence of severe acne, referral to a dermatologist is recommended for consideration of oral isotretinoin therapy

Hormonal treatment

Hormonal treatment can be an excellent option for females, especially if oral contraception is desirable.² It can be effective even if circulating androgen values are normal, because there may be increased sensitivity of the sebaceous follicle to a normal concentration of androgens. Relative contraindications include a history of smoking, family history of venous thromboembolism, and obesity.

Options for hormonal therapy are oestrogens or antiandrogens. In practice, in the UK, the most commonly used agent is Dianette combined oral contraceptive pill (COC). This is a combination of cyproterone acetate 2 mg (an antiandrogen) with ethinylestradiol 35 μ g. Improvement in acne may be

expected in 75–90% of patients with reduction in both comedones and inflammatory lesions.¹⁰ Some other COCs have also been shown to be of benefit in acne.¹¹

Hormonal treatment is generally used in combination with topical therapy. It is also helpful in patients where isotretinoin is being considered, because of its contraceptive effect.

Isotretinoin

Isotretinoin, an oral retinoid, is indicated for severe nodular or scarring acne. It may also be used for moderate acne, which is unresponsive to other treatments, rapidly relapsing, or associated with high psychological distress.²

Isotretinoin is extremely effective—a single course of 0.5–1 mg/kg/day for 4–6 months will achieve clearance in most cases of severe acne. Eighty per cent of patients will not need a further course. Isotretinoin is generally used as monotherapy.

Adverse effects of isotretinoin

Isotretinoin is associated with potentially serious side effects, most notably teratogenicity and mood changes (table 3). It can only be prescribed from hospital, and there are strict guidelines governing its use. The teratogenic effects are well documented and include central nervous system, central face, and cardiovascular abnormalities.¹² From 2005, all patients at potential risk of pregnancy—that is, females of child bearing age—must be enrolled in a pregnancy prevention plan which involves at least one form of contraception, negative pregnancy tests pre-treatment and monthly during treatment, and isotretinoin prescriptions for only one month of treatment at a time.¹³ This has considerable implications for resources in dermatology departments, and will inevitably result in reduced use of isotretinoin.

The situation regarding mood changes is less clear. Irritability, depression, and suicide have been reported in case reports and small studies since 1983. However, a review of the evidence by the retinoid working party on behalf of the British Association of Dermatologists concludes that suggestions of mood changes are currently unproven.¹³ Until more evidence is available, it is recommended that all patients given isotretinoin are questioned regarding psychiatric history and psychological symptoms, before and during treatment

INFANTILE ACNE

Case C

A 12 month old infant is referred for investigation of recurrent skin infections on the face. On examination, there are papules and pustules on the central cheeks

Table 3 Side effects of isotretinoin

<i>Dose related and predictable</i>
Dryness of skin and mucous membranes including nose, eyes, and lips
<i>Of particular concern</i>
Teratogenicity, during treatment and for 6 weeks after stopping
Mood change—highly publicised, unproven, but cause for concern
<i>Uncommon</i>
Facial erythema, eczema, hair loss, and photosensitivity
Myalgia and arthralgia
Abnormalities of liver function
Elevation of triglycerides and cholesterol values
Bacterial overgrowth, particularly <i>Staphylococcus aureus</i>
Benign intracranial hypertension

Table 4 Summary of treatments for acne			
	Mild	Moderate	Severe
First choice	Benzoyl peroxide (BPO)	<i>Comedone predominant</i> Benzoyl peroxide + topical retinoid <i>Inflammatory predominant</i> Benzoyl peroxide + topical antibiotic	Oral isotretinoin
Alternatives	Topical retinoid Azelaic acid Salicylic acid	Oral antibiotic + BPO Oral antibiotic + BPO + topical retinoid Azelaic acid Consider hormonal therapy for females	As for moderate acne

which mum says have been present since three months, and are getting worse. What is the likely diagnosis, and what are your treatment options?

The likely diagnosis is infantile acne. This is a rare form of acne, probably due to transplacental stimulation of adrenal androgens.¹⁴ It presents between 3–18 months of age and is more common in boys. Inflammatory lesions are most common, but comedones can occur. Infantile acne can last for several years, and is occasionally severe enough to cause scarring.

Mild disease responds to topical treatment with benzoyl peroxide, antibiotics, or retinoids. Oral erythromycin may be used. Oral tetracyclines are contraindicated in infants. Severe cases have been successfully treated with oral isotretinoin.¹⁵

COMPLEMENTARY AND PHYSICAL THERAPIES
Case D

Sally is 12 years old and has moderate acne. Sally’s father would like to know if any complementary or physical therapies are worth exploring as Sally dislikes creams, and father is worried about side effects from antibiotics. What is your advice?

A range of complementary therapies has been tried for acne. At the present time there is insufficient evidence to recommend them in place of standard therapy.

Zinc

A randomised comparative study showed that 31% of patients achieved at least two thirds reductions of inflammatory lesions with oral zinc 30 mg daily after 90 days, compared with 63% for minocycline.¹⁶

Comedone extraction and cautery

Comedone extraction can provide immediate benefit, but risks of incomplete extraction and tissue damage outweigh benefits.²

Light cautery to large comedones, which have not responded to conventional therapy, is sometimes used by dermatologists as an adjunct therapy in severe acne.¹⁴

Light and laser therapy

Many patients report that sunlight is beneficial for their acne, probably through antibacterial effects. Ultraviolet light regimens are no longer recommended because of concern about side effects, and reports that prolonged use can make acne worse.

There has been recent interest in photodynamic and laser therapy for acne, with promising early results from a study of pulsed-dye laser.¹⁷

SUMMARY

Acne is a common condition, which can be managed very effectively with a range of treatments. Treatment is aimed at improving appearance, discomfort, and psychological well being; and preventing scarring. A summary of recommended treatment options is given in table 4.
